**Other medication options**

Ibuprofen has been shown to be at least as effective as paracetamol but is more likely to produce gastrointestinal and renal adverse effects. One suspects that if ibuprofen is used as widely as paracetamol then inevitably its toxicity and adverse effects will become a problem.

Further population studies are required to establish the safety and pitfalls of a regimen using a limited number of doses of paracetamol and/or ibuprofen.

While aspirin is also effective, its widespread use cannot be recommended because of its gastrointestinal and platelet effects, and an association with the rare Reye’s syndrome.

**Summary**

- Paracetamol has a mild symptomatic benefit in childhood febrile illness
- Paracetamol toxicity data are increasingly worrying
- The various strengths of paracetamol mixtures are a major health hazard
- Paracetamol has not yet been shown to prevent febrile convulsions

**Recommendations**

1. There should be a concerted medical and pharmaceutical campaign to warn of the indiscriminate use of antipyretics in mild viral febrile illness in childhood.
2. An initial paracetamol dose of 15 mg/kg could be given, followed by three doses of 15 mg/kg over the next 24 hours if irritability continues.
3. No more than these four doses of paracetamol to be given for any one illness unless under medical or pharmacist supervision.
4. Each bottle of paracetamol mixture should have the mg/mL concentration in huge letters on the label, with the words ‘Beware, potentially toxic’ on the 100 mg/mL bottle. Consideration should be given to withdrawal of all but the lowest strength.
5. Treat the child, not the thermometer.

**REFERENCES**

**Self-test questions**

The following statements are either true or false (answers on page 67)

5. Viral shedding times are reduced by paracetamol.
6. Antipyretic prophylaxis is effective at preventing febrile seizures.

**Paracetamol: overused in childhood fever – a consumer perspective**

*Dell Horey, Maternity Alliance; and Helen Hopkins, Consumers’ Health Forum*

Dr Hewson’s paper recommends a concerted medical and pharmaceutical campaign to warn against the indiscriminate use of medicines such as paracetamol to treat mild viral fevers in children. Perhaps a more appropriate focus for the campaign would be the safe and appropriate use of paracetamol in childhood illnesses, including information about other measures parents can use to help their child feel more comfortable while recovering.

Parents need the information in recommendations 2 to 4 of the paper. They need to know what dose of paracetamol to give,
Treating head lice

Orli Wargon, Dermatologist, Sydney

SYNOPSIS

Head lice (Pediculosis capitis) is a common condition in children. It is usually detected in schools, when children are seen scratching their heads. The diagnosis can be confirmed by finding live adult lice or viable eggs. Lice are usually adequately treated with an over-the-counter topical permethrin preparation. Treatment failure results from inadequate therapy, re-infection, resistance to the insecticide or an underlying immunosuppression. Prescription drugs such as ivermectin may be needed in more difficult cases.

Index words: Pediculosis capitis, permethrin, maldison, ivermectin.

Background

Blood sucking lice of the order Anoplura are successful obligate ectoparasites of humans.1 Pediculus humanus capitis, the head louse, is a distinct clinical form. It clings to hair with its claws and feeds by sucking blood from the scalp. Its life cycle is about 17–20 days with eggs hatching 7–10 days after they are laid, and adults are fully developed about 10 days later.2 Head lice spread by head to head contact.

Diagnosis

A child found to be scratching their head at school is often checked by the teacher, school nurse or public health personnel. If they are well trained or experienced they will look for live adult lice on the crown of the scalp, immature nymphs or viable eggs. Empty shells or nits adhere to the hair, 1 cm from the scalp surface, with a glue-like substance. They are unlike seborrhoeic scales, hair casts and hair spray, which are easily brushed off.

Treatment

Three types of insecticide are marketed worldwide. In my local pharmacies all insecticide products for head lice are either permethrins 10 mg/mL as shampoos, lotions or creme rinses or maldison products with 0.5% alcohol bases, 1% foam bases, shampoos or soaking solutions.

Alcoholic lotions have greater ovicidal activity3, the creme rinses are less ovicidal than liquids and lotions4 and shampoo formulations have low ovicidal activity and may not kill eggs.5 In theory, one application should kill all lice and eggs. However, in vitro studies3,4 suggest that some eggs can survive and require a second application after seven days. Surviving eggs can cause reinfestation if not removed.

Everyone who has been in contact with the patient should be examined and treated if affected. It is also advisable to wash all clothes, head gear, towels, bed linen, combs and brushes as head lice can survive away from the human host for about three days and eggs can survive for up to 10 days.

Permethrin (3 phenoxybenzyl cis trans3(2,2-dichlorvinyl)-2,2 dimethyl cyclopropane carboxylate) is a synthetic pyrethroid. It acts on parasitic nerve cell membranes and has low mammalian toxicity, but incomplete ovicidal properties.6 Patients apply permethrin to the hair for 10 minutes then wash...
